Strategies to Prevent Rolling Contact Fatigue on Railroad Wheels & Rails

Harry Tournay
Sabri Cakdi

Presentation to SAE FD&E
May 6, 2015

Transportation Technology Center,
Pueblo, CO

What is Rolling Contact Fatigue (RCF)?

Total Life of Wheel & Rail Surfaces

- ◆ **On and (up to a maximum of 1 inch) beneath the contact band on wheel & rail.**
- ◆ **One or a combination of the following mechanisms:**
 - Wear
 - Material flow
 - Crack nucleation
 - Crack initiation
 - Crack propagation
 - Residual stress formation
 - Material break-out
 - Brittle failure

Objective

Maximize Wheel & Rail Life

◆ Reduced wheel tread damage resulting from:

- “Scuffing” & HIW
(consequence of high steering tractions)
- Shelling & HIW
(consequence of delamination)

HIW due to high steering tractions

◆ Reduced rail RCF (wear, material flow & cracking) resulting from:

- High lead axle low rail steering tractions
- Spalling (high contact stresses)

HIW due to shelling

Rail Wear & Material Flow

Rail Spalling

Objective

Prevent Wheel & Rail Failure

◆ **Wheel Failure:**

- Vertical Split Rims (VSR) & flanges (VSF)
- Shattered Rims (SR)

Vertical Split Rim

Shattered Rim

◆ **Rail Failure:**

- Transverse defect (TD)
- May develop from one or a combination of:
 - ▲ RCF
 - ▲ Reverse bending
 - ▲ Thermal stresses

Problem Size

Estimated Industry Costs

◆ \$800M

- Approximately \$400M in wheel replacement cost
- Approximately \$400M in rail grinding & replacement

Tread (Surface) Scuffing Damage

◆ Findings

- Slip can occur:
 - ▲ Under high specific loads in the contact patch
 - ▲ At tractions substantially less than for limiting friction / complete slip
- CONTACT modeling confirms this suggestion & that resulting surface stresses can approach or exceed the ultimate tensile stress of the wheel material under 286,000-pound operation

Von Mises Stress on
surface of contact patch

Tread (Surface) Scuffing Damage

◆ Review Creep Mechanism

- Generation of regions of adhesion & slip

Tread (Surface) Scuffing Damage

◆ Prediction

(Based on linear model)

- Damage initiation in a 3-piece truck occurs:
 - ▲ In 7-degree curve:
 - Underbalance conditions
 - At 70°F
 - ▲ In shallower curves given:
 - Underbalance speeds
 - Higher wheel temperatures

◆ Suggested Initiating Mechanism

- Von Mises stresses “tear-out” material from the surface of the contact patch
- Possibly exacerbated by:
 - ▲ Surface microcorrugation
 - ▲ High temperatures caused by slip and tearing-out process

Tread (Surface) Scuffing Damage

◆ Suggested Propagating Mechanism

- A void is created on the surface of the contact patch
- The void allows the initiation of material flow near the surface of the wheel
- Material flow initiates cracks
- Cracks propagate down to the area of maximum shear stress (τ_{\max})
- Pieces break out of the surface of the wheel at the depth of τ_{\max}
- Process is exacerbated by the ingress of ice causing winter HIW

Rail Scuffing Damage

◆ Scuffing damage model likely to be applicable to rail:

Scuffing Marks?
(not cracks?)

Crack formation & material break-out:

- Why not at the depth of the maximum shear stress as occurs in wheels?
- Is this shallower break-out because of the higher strength of wheel steels?
- Is this shallower break-out what we & TTX are observing with Class D wheel steels?

in Revenue Service**

Likely shelling at the depth of
the maximum
shear stress

Tread Shelling

◆ Initiated by subsurface fatigue

- Maximum shear stress (τ_{\max}) approximately 3/16 inch beneath the tread surface
- Magnitude & depth substantially independent of surface tractions
- Result: Delamination

Low Traction

High Traction

- Break out of tread to form:

Tread Shelling

◆ Subsurface fatigue analysis

- Simple analysis using T_{\max} would suggest early failure
- Analysis is exacerbated by multi-axial stress condition:

Tread Shelling

◆ Robust subsurface fatigue analysis model / method could assist in design & choice of new generation wheel & rail steels:

- Maximum flaw size & location in wheels & rails
 - ▲ As produced
 - ▲ After machining / grinding
- Fatigue life of wheels / rails
- Wheel steel strength vs. fracture toughness to avoid
 - ▲ Delamination / vertical split rims
 - ▲ Shattered rims
- Role of residual stresses
- Role of stress / strain linearity & yield stress in fatigue life
- Influence of grain size on fatigue life

Wheel Failure Mechanisms: VSR

♦ Vertical Split Rim: Review proposed formation mechanism

- VSR & VSF associated with delamination

Delamination implies:

- Shear stresses are no longer transferred across the delamination interface
- The contact model is no longer Hertzian

TTCI Wheel Failure Mechanisms: VSR

◆ VSR / VSF:

- Delamination causes the delaminated material to cold-roll introducing residual stresses

Consequently tensile stresses are concentrated at the ends of the delamination because shear stress cannot be transferred across delamination

Field side of wheel

Compression

Tension

Upper laminate in compression may induce a state of tension at the field side end of the laminate: this, together with a field side vertical load, could induce a vertical crack and resulting VSR.

◆ Original Objective:

- Measure residual stresses in both the delamination & the body of the wheel for input to finite element analysis
- X-ray diffraction analysis of residual stresses did not find a difference
- Subsequently advised that this method is too shallow (order of microns thick)

◆ Metallurgical analysis finds martensite along delamination interface

Wheel Failure Mechanisms: VSR

◆ Presence of martensite along delamination interface:

- Suggests rubbing & flash cooling – commensurate with a strain differential between the delamination & the body of the wheel – in support of the proposed mechanism?

- Might, however, suggest that the presence of martensite itself is a contributing root cause of the downward branching of the crack not necessarily at the end of the delamination

◆ In other words VSR formation may require:

- Tensile residual tensile stresses as suggested by the model
- Martensite formed by differential rubbing & flash cooling

◆ What about the role of thermal braking stresses?

Wheel Failure Mechanisms: VSR

- ◆ **Evidence in support for the mechanism from partial VSR formation:** *(2008 BNSF study group report)*

◆ Questions: *If delamination found to be root cause of VSR:*

- *Should a HPW not be specified to be cleaner in the region beneath the tape line?*
- *Should the capabilities of UT technology not be explored for this specific condition?*
- *Limit $\leq 0.5\text{mm}$?*

AAR block evaluation

- UT suppliers being approached to offer existing instrumentation for evaluation

Kinematic concept of a railway wheelset

- ◆ *Wheels of a di-cone run on different diameters (rolling radii) to accommodate the difference in distance traveled between the outer & inner wheel in a curve*
- ◆ $(r_o - r_i) / g = r_w / R_c$

Comment:

- ◆ *This is termed a “pure rolling” position*

Kinematic concept of a railway wheelset

- ◆ *Wheels of a di-cone run centralize the wheelset on tangent track:*
 - *When laterally displaced from the center of the track*
 - *Accommodating diameter differences between the wheels (due to tolerances on machining; wear) – this within the gage clearance provided*

Comment:

- ◆ *If this motion takes place in a sustained manner with regular flange contact, it is termed “hunting”*

SRI 1C Root Causes of Wheel/Rail RCF

Support RCFS Construction & Commissioning

- ◆ **RCFS commissioned on schedule at TTC on March 11, 2015.**
- ◆ **Site preparation & support 80% complete**
- ◆ **Initial wheel tread scuffing tests in process to:**
 - Verify RCFS can produce RCF
 - Install & test:
 - ▲ Vacuum debris removal.
 - ▲ Instrumented rail & wheelset & data integration with MTS system
 - ▲ Surface monitoring cameras.
 - Develop robust test protocols to ensure traceability of specimens & repeatability of tests.
 - Develop & update safety protocols reflecting platform & access control status
